Abstract

Keywords: Cell free metabolism, Mathematical modeling

Introduction

18

20

21

Mathematical modeling has long contributed to our understanding of metabolism. Decades before the genomics revolution, mechanistically, structured metabolic models arose from the desire to predict microbial phenotypes resulting from changes in intracellular or extracellular states [1]. The single cell E. coli models of Shuler and coworkers pioneered the construction of large-scale, dynamic metabolic models that incorporated multiple, requlated catabolic and anabolic pathways constrained by experimentally determined kinetic parameters [2]. Shuler and coworkers generated many single cell kinetic models, including single cell models of eukaryotes [3, 4], minimal cell architectures [5], as well as DNA sequence based whole-cell models of E. coli [6]. Conversely, highly abstracted kinetic frameworks, such as the cybernetic framework, represented a paradigm shift, viewing cells as growth-optimizing strategists [7]. Cybernetic models have been highly successful at predicting metabolic choice behavior, e.g., diauxie behavior [8], steady-state multiplicity [9], as well as the cellular response to metabolic engineering modifications [10]. Unfortunately, cybernetic models also suffer from an identifiability challenge, as both the kinetic 15 parameters and an abstracted model of cellular objectives must be estimated simultane-16 ously. 17

In the post genomics world, large-scale stoichiometric reconstructions of microbial metabolism popularized by static, constraint-based modeling techniques such as flux balance analysis (FBA) have become standard tools [11]. Since the first genome-scale stoichiometric model of *E. coli*, developed by Edwards and Palsson [12], well over 100 organisms, including industrially important prokaryotes such as *E. coli* [13] or *B. subtilis* [14], are now available [15]. Stoichiometric models rely on a pseudo-steady-state assumption to reduce unidentifiable genome-scale kinetic models to an underdetermined linear algebraic system, which can be solved efficiently even for large systems. Traditionally, stoichiometric models have also neglected explicit descriptions of metabolic regulation

and control mechanisms, instead opting to describe the choice of pathways by prescribing an objective function on metabolism. Interestingly, similar to early cybernetic models, the most common metabolic objective function has been the optimization of biomass formation [16], although other metabolic objectives have also been estimated [17]. Recent 30 advances in constraints based modeling have overcome the early shortcomings of the 31 platform, including capturing metabolic regulation and control [18]. Thus, modern con-32 straints based approaches have proven extremely useful in the discovery of metabolic 33 engineering strategies and represent the state of the art in metabolic modeling [19, 20]. 34 However, genome scale kinetic models of industrial important organisms such as E coli 35 have yet to be constructed.

Cell free systems offer many advantages for the study and modeling of metabolism 37 when compared to traditional in vivo processes. Central amongst these advantages, is 38 direct access to the microbial biosynthetic machinery without the interference of a cell wall. This allows us to control as well as interrogate the chemical environment while the biosynthetic machinery is operating, potentially at a fine time resolution. Second, 41 it also allows us to study biological processes without the complications of cell growth that would normally occur with in vivo processes. Cell free protein synthesis (CFPS) systems are arguably the most prominent examples of cell free biology in use today [21]. However, CFPS is not a new idea; CFPS in crude E. coli extracts has been used since the 1960s to explore fundamentally important biological mechanisms [22, 23]. Today, cell free systems are used in a variety of applications ranging therapeutic protein production [24] to synthetic biology [25]. Many of the challenges to whole-genome kinetic modeling are overcome in a cell-free system. For example, there is no complex transcriptional 49 regulation to consider, transient metabolic measurements are easier to obtain, and we no 50 longer have to consider cell growth. In this case, whole cell dynamic metabolic models 51 may be possible for important organisms such as E. coli. Thus, cell-free operation holds several significant advantages for model development, identification and validation.

In this study, we present an effective biochemical network modeling framework for 54 building dynamic metabolic models. The key innovation of our approach is the seamless integration of simple effective rules encoding complex regulation, with traditional kinetic 56 pathway modeling. This integration allows the description of complex regulatory interac-57 tions, such as time-dependent allosteric regulation of enzyme activity, in the absence of specific mechanistic information. Moreover, the rules are easy to understand, easy to for-59 mulate and do not rely on overarching theoretical abstractions, or restrictive assumptions. 60 We tested our approach by modeling the time evolution of hypothetical cell free metabolic 61 networks. In particular, we tested whether our effective modeling approach could de-62 scribe classically expected behavior, and second whether we could simultaneously esti-63 mate kinetic parameters and regulatory connectivity, in the absence of specific mecha-64 nistic knowledge, from synthetic experimental data. Toward these questions, we explored five hypothetical cell-free networks. Each network shared the same enzymatic connectivity, but had different allosteric regulatory connectivity. We found that simple effective 67 rules, when integrated with traditional enzyme kinetic expressions, captured complex allosteric patterns such as ultrasensitivity, or non-competitive inhibition in the absence of specific mechanistic information. Moreover, when integrated into network models, these rules captured classical regulatory patterns such as product induced feedback inhibition. Lastly, we simultaneously estimated kinetic parameters and discriminated between competing regulatory structures, using synthetic data in combination with a modified particle swarm approach. While only a proof-of-concept, [FINISH ME].

99

Formulation and properties of cell free effective models. We developed two proofof-concept metabolic networks to investigate the features of our effective biochemical 77 network modeling approach (Fig. 1). In both examples, substrate S was converted to the 78 end-products P₁ and P₂ through a series of enzymatically catalyzed reactions, including a branch point at hypothetical metabolite M_2 . Several of these reactions involved cofactor dependence (AH or A), and various allosteric regulation mechanisms. Network A included feedback inhibition of the initial pathway enzyme (E_1) by pathway end products P_1 and P_2 (Fig. 1A). On the other hand, network B involved feedback inhibition of E_1 by P_2 and E_6 by P_1 (Fig. 1B). In both networks, branch point enzymes E_3 and E_6 were subject to feed-forward activation by cofactor AH. Lastly, enzyme activity was assumed to decay according to a first-order rate law in both cases. Allosteric regulation of enzyme activity was represented using a novel rule-based strategy, similar in spirit to the Constrained 87 Fuzzy Logic (cFL) approach of Lauffenberger and coworkers [26]. In this formulation, Hill-like transfer functions were used to calculate the influence of metabolite abundance 89 upon target enzyme activity. When an enzyme was potentially sensitive to more than one 90 regulatory influence, logical rules were used to select which transfer function regulated 91 enzyme activity at any given time (Fig. 2). Thus, our test networks involved important 92 features such as cofactor recycling, enzyme activity and metabolite dynamics, as well 93 as multiple overlapping allosteric regulatory mechanisms. As such, developing our ef-94 fective modeling approach using these simple problems gave us valuable insight into the 95 development of larger network models, without the complication of network size. 96

The rule based regulatory strategy approximated the behavior of classical allosteric activation and inhibition mechanisms (Fig. 3). We first explored feed-forward substrate activation of enzyme activity (for both positive and negative cooperativity). Consistent with classical data, the rule based strategy predicted a sigmoidal relationship between sub-

strate abundance and reaction rate as a function of the cooperativity parameter (Fig. 3A). For cooperativity parameters less than unity, increased substrate abundance decreased the reaction rate. This was consistent with the idea that substrate binding decreases at regulatory sites negatively impacts the ability of the enzyme to bind substrate at the active site. On the other hand, as the cooperativity parameter increased past unity, the rate of conversion of substrate S to product P by enzyme E approached a step function. In the presence of an inhibitor, the rule based strategy predicted non-competitive like behavior as a function of the cooperativity parameter (Fig. 3B). When the control gain parameter, κ_{ij} in Eqn. (10), was greater than unity, the inhibitory force was directly proportional to the cooperativity parameter, η in Eqn. (10). Thus, as the cooperativity parameter increased, the maximum reaction rate decreased (Fig. 3B, orange). However, when the gain parameter was less than unity, enzyme inhibition increased with decreasing cooperativity, i.e., smaller η yielded increased inhibition (Fig. 3B). Interestingly, our rule based approach was unable to directly simulate competitive inhibition of enzyme activity. For competitive inhibitors, the kinetic component of our rate, \bar{r}_j in (3), could be modified to account for the inhibition (data not shown). Taken together, the rule based strategy captured classical regulatory patterns for both enzyme activation and inhibition. Thus, we are able to model complex kinetic phenomena such as ultrasensitivity, despite an effective description of reaction kinetics.

End product yield was controlled by feedback inhibition, while selectivity was controlled by branch point enzyme inhibition (Fig. 4). A critical test of our modeling approach was to simulate networks with known behavior. If we cannot reproduce the expected behavior of simple networks, then our effect modeling strategy, and particularly the rule-based approximation of allosteric regulation, will not be feasible for large scale problems. We considered two cases, control on/off, for each network configuration. Each of these cases had identical kinetic parameters and initial conditions; the *only* differences between

the cases was the allosteric regulation rules, and the control parameters associated with these rules. As expected, end product accumulation was larger for network A when the 128 control was off (no feedback inhibition of E_1 by P_1 and P_2), as compared to the on case 129 (Fig. 4A). We found this behavior was robust to the choice of underlying kinetic parame-130 ters, as we observed that same qualitative response across an ensemble of randomized 131 parameter sets (N = 100). The control on/off response of network B was more subtle. In 132 the off case, the behavior was qualitatively similar to network A. However, for the on case, 133 flux was diverted away from P_2 formation by feedback inhibition of E_6 activity at the M_2 134 branch point by P_1 (Fig. 4B). Lower E_6 activity at the M_2 branch point allowed more flux 135 toward P₁ formation, hence the yield of P₁ also increased (Fig. 4C). Again, the control 136 on/off behavior was robust to changes kinetic parameters, as the same qualitative trend 137 was conserved across an ensemble of randomized parameters (N = 100). Taken together, 138 these simulations suggested that the rule based allosteric control concept could robustly 139 capture expected feedback behavior. 140

Estimating parameters and effective allosteric regulatory structures. A critical chal-141 lenge for any dynamic model is the estimation of kinetic parameters. For metabolic pro-142 cesses, there is also the added challenge of identifying the regulation and control struc-143 tures that manage metabolism. Of course, these issues are not independent; any descrip-144 tion of enzyme activity regulation will be a function of system state, which in turn depends 145 upon the kinetic parameters. For cell free systems, regulated gene expression has been 146 removed, however, enzyme activity regulation is still operational. We explored this link-147 age by estimating model parameters from synthetic data using both network structures. 148 We generated noise-corrupted synthetic measurements of the substrate S, intermediate 149 M₅ and end-product P₁ approximately every 20 min using network A. We then generated 150 an ensemble of model parameter estimates by minimizing the difference between model 151 simulations and the synthetic data using particle swarm optimization (PSO), starting from random initial parameter guesses. The estimation of kinetic parameters was sensitive to the choice of regulatory structure (Fig. 5). PSO identified an ensemble of parameters that bracketed the mean of the synthetic measurements in less than 1000 iterations when the control structure was correct (Fig. 5A and B). However, with control mismatch (network B simulated with network A parameters), the model simulations were not consistent with the synthetic data (Fig. 5C and D). Taken together, these results suggested that we could perhaps simultaneously estimate both parameters and network control architectures, as incorrect control structures would be manifest as poor model fits.

We modified our particle swarm identification strategy to simultaneously search over both kinetic parameters and putative control structures. In addition to our initial networks, we constructed three additional presumptive network models, each with the same enzymatic connectivity but different allosteric regulation of the pathway enzymes (Fig. 6). We then initialized a population of particles, each with one of the five potential regulatory programs, and randomized kinetic parameters. Thus, we generated an initial population of particles that had both different kinetic parameters as well as different control structures. We biased the distribution of the particle population according to our a prior belief of the correct regulatory program. To this end, we considered three different priors, a uniform distribution where each putative regulatory structure represented 20% of the population, and two mixed distributions that were either positively or negatively biased towards the correct structure (network A). In both the positively biased, and uniform cases the particle swarm clearly differentiated between the true or closely related structures and those that were materially different (Fig. 7). As expected, the positively biased population (40% of the initial particle population seeded with network A) gave the best results, where the correct structure was preferentially identified (Fig. 7A). On the other hand, when given a uniform distribution, the PSO approach identified a combination of network A and network C as the most likely control structures (Fig. 7B). Network A and C differ by the regulatory

connection between the end-product P_2 and enzyme E_1 ; in network A end-product P_2 was assumed to inhibit E_1 while in network C end-product P_2 activated E_1 . Lastly, when the initial population was biased towards a incorrect structures (initial population seeded with 90% incorrect structures), the particle swarm *misidentified* the correct allosteric structure (Fig. 7C). Interestingly, while each particle swarm identified parameter sets that minimized the simulation error, the estimated parameter values were not necessarily similar to the true parameters. The angle between the estimated and true parameters was not consis-tently small across the swarms (identical parameters would give an angle of zero). This suggested that our particle swarm approach identified a sloppy ensemble, i.e., parame-ter estimates that were individually incorrect but collectively exhibited the correct model behavior.

We calculated control program output and scaled metabolic flux for the positively, uniformly and negatively biased particle swarms (Fig. 8). Network A and network C models from the positively (Fig. 8A) and uniformly (Fig. 8B) biased particle swarms showed similar operational patterns, despite differences in kinetic parameters and control structures. While models from the negatively biased population had error values similar to the correct structures in the previous swarms, they have different flux and control profiles (Fig. 8C). In all cases, irregardless of network configuration or parameter values, the rate of enzyme decay was small compared to the other fluxes, and all networks had qualitatively similar trends for E_3 and E_6 control. Moreover, consistent with the correct model structure, production of end-product P_1 was the preferred branch for all model configurations. However, there was variability in P_2 production flux across the population of models, especially for the uniform swarm when compared with the other cases. High P_1 branch flux resulted in end product inhibition of E_1 in both network A and network C, however in network D and E high P_1 flux induced E_1 activation. These trends were manifested in different flux profiles, where the negatively biased population appeared more uniform across the pop-

ulation compared with the other swarms, and had higher E_1 specific activity. Interestingly, the behavior of network A and network C highlighted an artifact of our integration rule; 206 both a positive or negative feedback connection from P_2 to \mathcal{E}_1 were ignored because the 207 P_1 inhibition of E_1 was dominate. Thus, while theoretically distinct, network A and network 208 C appeared operationally to the PSO algorithm to be that same network. On the other 209 hand, networks B, D and E showed distinct behavior that was not consistent with the true 210 network. These architectures exhibited either limited inhibition (network B) or activation 211 (network D and E) of E_1 activity, resulting in significantly different metabolic flux profiles. 212 However, the PSO was able to find low error parameter solutions, despite the mismatch 213 in the control structures. Taken together, these results suggested that a uniform sampling 214 approach could potentially yield an unbiassed estimate of both kinetic parameters control 215 structures.

7 Discussion

In this study, we presented an effective kinetic modeling strategy to dynamically simu-218 late biochemical networks. Our proposed strategy integrated traditional kinetic modeling 219 with an effective rules based approach to dynamically describe metabolic regulation and 220 control. We tested this approach by developing kinetic models of hypothetical cell free 221 metabolic networks. In particular, we tested whether our effective modeling approach 222 could describe classically expected behavior, and second whether we could simultane-223 ously estimate kinetic parameters and regulatory connectivity, in the absence of specific 224 mechanistic knowledge, from synthetic experimental data. Toward these questions, we 225 explored five hypothetical cell-free networks. In each network, a substrate S was converted to the end-products P₁ and P₂ through a series of enzymatically catalyzed re-227 actions, including a branch point at a hypothetical metabolite M₂. Each network also included the same cofactors and cofactor recycle architecture. However, while all five networks shared the same enzymatic connectivity, each had different allosteric regulatory 230 connectivity. We found that simple effective rules, when integrated with traditional enzyme 231 kinetic expressions, could capture complex allosteric patterns such as ultrasensitivity, or 232 non-competitive inhibition in the absence of specific mechanistic information. Moreover, 233 when integrated into network models, these rules captured classical regulatory patterns 234 such as product induced feedback inhibition. Lastly, we simultaneously estimated kinetic 235 parameters and discriminated between competing regulatory structures, using synthetic 236 data in combination with a modified particle swarm approach. 237

While the results of this study were encouraging, there are several critical next steps
that must be accomplished before we can model genome scale cell free metabolic networks.

41 Materials and Methods

Formulation and solution of the model equations. We used ordinary differential equations (ODEs) to model the time evolution of metabolite (x_i) and scaled enzyme abundance (ϵ_i) in hypothetical cell free metabolic networks:

$$\frac{dx_i}{dt} = \sum_{j=1}^{\mathcal{R}} \sigma_{ij} r_j(\mathbf{x}, \epsilon, \mathbf{k}) \qquad i = 1, 2, \dots, \mathcal{M}$$
 (1)

$$\frac{d\epsilon_i}{dt} = -\lambda_i \epsilon_i \qquad i = 1, 2, \dots, \mathcal{E}$$
 (2)

where \mathcal{R} denotes the number of reactions, \mathcal{M} denotes the number of metabolites and \mathcal{E} denotes the number of enzymes in the model. The quantity $r_i(\mathbf{x}, \epsilon, \mathbf{k})$ denotes the 246 rate of reaction j. Typically, reaction j is a non-linear function of metabolite and enzyme 247 abundance, as well as unknown kinetic parameters \mathbf{k} ($\mathcal{K} \times 1$). The quantity σ_{ij} denotes 248 the stoichiometric coefficient for species i in reaction j. If $\sigma_{ij} > 0$, metabolite i is produced 249 by reaction j. Conversely, if $\sigma_{ij} > 0$, metabolite i is consumed by reaction j, while $\sigma_{ij} = 0$ 250 indicates metabolite i is not connected with reaction j. Lastly, λ_i denotes the scaled 251 enzyme degradation constant. The system material balances were subject to the initial 252 conditions $\mathbf{x}(t_o) = \mathbf{x}_o$ and $\epsilon(t_o) = 1$ (initially we have 100% cell-free enzyme abundance). 253 Each reaction rate was written as the product of two terms, a kinetic term (\bar{r}_i) and a 254 regulatory term (v_i) : 255

$$r_{j}\left(\mathbf{x},\epsilon,\mathbf{k}\right) = \bar{r}_{j}v_{j} \tag{3}$$

We used multiple saturation kinetics to model the reaction term \bar{r}_j :

$$\bar{r}_j = k_j^{max} \epsilon_i \left(\prod_{s \in m_j^-} \frac{x_s}{K_{js} + x_s} \right) \tag{4}$$

where k_j^{max} denotes the maximum rate for reaction $j,\ \epsilon_i$ denotes the scaled enzyme ac-

tivity which catalyzes reaction j, and K_{js} denotes the saturation constant for species s in reaction j. The product in Eqn. (4) was carried out over the set of *reactants* for reaction j (denoted as m_j^-).

The allosteric regulation term v_j depended upon the combination of factors which influenced the activity of enzyme i. For each enzyme, we used a rule based approach to select from competing control factors (Fig. 2). If an enzyme was activated by m metabolites, we modeled this activation as:

$$v_{j} = \max(f_{1j}(x), \dots, f_{mj}(x))$$
 (5)

where $0 \le f_{ij}(x) \le 1$ was a regulatory transfer function that calculated the influence of metabolite i on the activity of enzyme j. Conversely, if enzyme activity was inhibited by a m metabolites, we modeling this inhibition as:

$$v_{j} = 1 - \max(f_{1j}(x), \dots, f_{mj}(x))$$
 (6)

Lastly, if an enzyme had both m activating and n inhibitory factors, we modeled the regulatory term as:

$$v_j = \min\left(u_j, d_j\right) \tag{7}$$

270 where:

$$u_j = \max_{j^+} (f_{1j}(x), \dots, f_{mj}(x))$$
 (8)

$$d_{j} = 1 - \max_{j^{-}} (f_{1j}(x), \dots, f_{nj}(x))$$
(9)

The quantities j^+ and j^- denoted the sets of activating, and inhibitory factors for enzyme j. If an enzyme had no allosteric factors, we set $v_j=1$. There are many possible

functional forms for $0 \le f_{ij}(x) \le 1$. However, in this study, each individual transfer function took the form:

$$f_i(\mathbf{x}) = \frac{\kappa_{ij}^{\eta} x_j^{\eta}}{1 + \kappa_{ij}^{\eta} x_j^{\eta}} \tag{10}$$

where x_j denotes the abundance of metabolite j, and κ_{ij} and η are control parameters. 275 The κ_{ij} parameter was species gain parameter, while η was a cooperativity parameter 276 (similar to a Hill coefficient). The model equations were encoded using the Octave pro-277 gramming language, and solved using the LSODE routine in Octave [27]. 278

Estimation of model parameters and structures from synthetic experimental data.

Model parameters were estimated by minimizing the difference between simulations and 280 synthetic experimental data (squared residual):

$$\min_{\mathbf{k}} \sum_{\tau=1}^{\mathcal{T}} \sum_{j=1}^{\mathcal{S}} \left(\frac{\hat{x}_j(\tau) - x_j(\tau, \mathbf{k})}{\omega_j(\tau)} \right)^2$$
(11)

where $\hat{x}_{j}\left(\tau\right)$ denotes the measured value of species j at time τ , $x_{j}\left(\tau,\mathbf{k}\right)$ denotes the sim-282 ulated value for species j at time τ , and $\omega_{j}(\tau)$ denotes the experimental measurement variance for species i at time τ . The outer summation is respect to time, while the inner summation is with respect to state. We approximated a realistic model identification sce-285 nario, assuming noisy experimental data, limited sampling resolution (approximately 20 286 minutes per sample) and a limited number of measurable metabolites.

283

284

287

288

29

292

We minimized the model residual using Particle swarm optimization (PSO) [28]. PSO uses a swarming metaheuristic to explore parameter spaces. A strength of PSO is its ability to find the global minimum, even in the presence of potentially many local minima, by communicating the local error landscape experienced by each particle collectively to the swarm. Thus, PSO acts both as a local and a global search algorithm. For each iteration, particles in the swarm compute their local error by evaluating the model equations using their specific parameter vector realization. From each of these local points, a globally best error is identified. Both the local and global error are then used to update the parameter estimates of each particle using the rules:

$$\Delta_i = \theta_1 \Delta_i + \theta_2 \mathbf{r}_1 \left(\mathcal{L}_i - \mathbf{k}_i \right) + \theta_3 \mathbf{r}_2 \left(\mathcal{G} - \mathbf{k}_i \right) \tag{12}$$

$$\mathbf{k}_i = \mathbf{k}_i + \mathbf{\Delta}_i \tag{13}$$

where $(\theta_1,\theta_2,\theta_3)$ are adjustable parameters, \mathcal{L}_i denotes local best solution found by particle i, and \mathcal{G} denotes the best solution found over the entire population of particles. The quantities r_1 and r_2 denote uniform random vectors with the same dimension as the number of unknown model parameters ($\mathcal{K} \times 1$). In thus study, we used $(\theta_1,\theta_2,\theta_3)=(1.0,0.05564,0.02886)$, which was taken from XXX. The quality of parameter estimates was measured using two criteria, goodness of fit (model residual) and angle between the estimated parameter vector \mathbf{k}_j and the true parameter set \mathbf{k}^* :

$$\alpha_j = \cos^{-1}\left(\frac{\mathbf{k}_j \cdot \mathbf{k}^*}{\|\mathbf{k}_j\| \|\mathbf{k}^*\|}\right) \tag{14}$$

If the candidate parameter set \mathbf{k}_j were perfect, the residual between the model and synthetic data and the angle between \mathbf{k}_j and the true parameter set \mathbf{k}^* would be equal to zero.

307

308

309

311

312

We modified our PSO implementation to simultaneously search over kinetic parameters and putative model control structures. In the combined case, each particle potentially carried a different model realization in addition to a different kinetic parameter vector. We kept the update rules the same (along with the update parameters). Thus, each particle competed on the basis of goodness of fit, which allowed different model structures to contribute to the overall behavior of the swarm. We considered five possible model

structures (A through E), where network A was the correct formulation (used to generate the synthetic data). We considered a population N = 100 particles, where each particle in the swarm was assigned a model structure, and a random parameter vector. The PSO algorithm, model equations, and the objective function were encoded and solved in the Octave programming language [27].

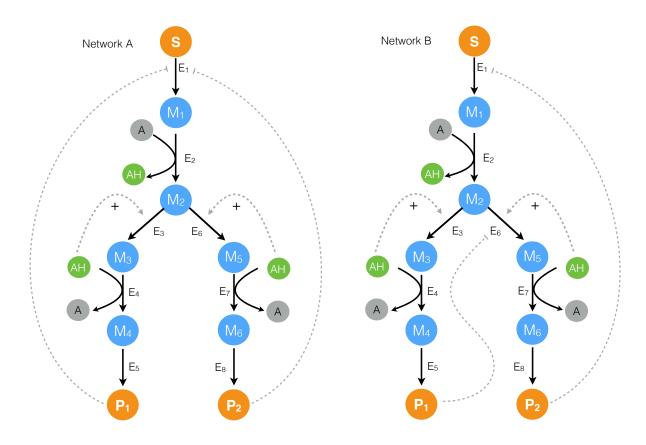

Fig. 1: Proof of concept cell-free metabolic networks considered in this study. Substrate S is converted to products P_1 and P_2 through a series of chemical conversions catalyzed by enzyme(s) E_j . The activity of the pathway enzymes is subject to both positive and negative allosteric regulation.

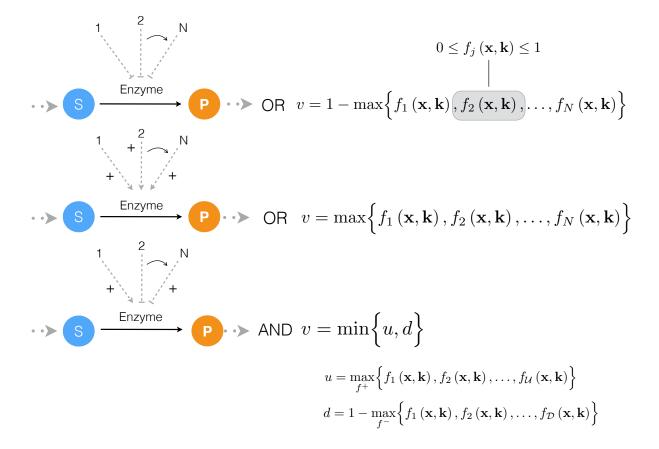

Fig. 2: Schematic of rule based allosteric enzyme activity control laws. Traditional enzyme kinetic expressions e.g., Michaelis–Menten or multiple saturation kinetics are multiplied by an enzyme activity control variable $0 \le v_j \le 1$. Control variables are functions of many possible regulatory factors encoded by arbitrary functions of the form $0 \le f_j(\mathcal{Z}) \le 1$. At each simulation time step, the v_j variables are calculated by evaluating integration rules such as the max or min of the set of factors f_1, \ldots influencing the activity of enzyme E_j .

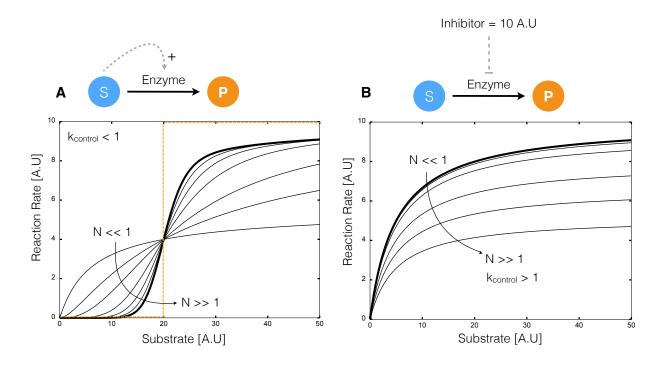

Fig. 3: Kinetics of simple transformations in the presence of activation and inhibition. **A**:The conversion of substrate S to product P by enzyme E was activated by S. For a fixed control gain parameter $k_{control}$, the reaction rate approached a step for increasing control order N. **B**:The conversion of substrate S to product P by enzyme E with inhibitor I. For a fixed control gain parameter $k_{control}$, the reaction rate approximated non-competitive inhibition for increasing control order N.

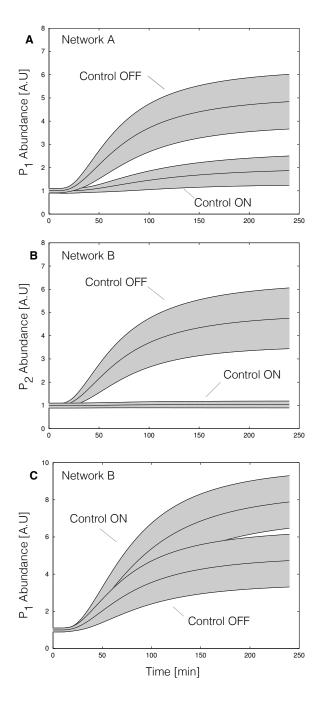

Fig. 4: ON/OFF control simulations for network A and network B for an ensemble of kinetic parameter sets versus time (N = 100). For each case, N = 100 simulations were conducted using kinetic and initial conditions generated randomly from a hypothetical true parameter set. The gray area represents \pm one standard deviation surrounding the mean. Control parameters were fixed during the ensemble calculations. A: End-product P₁ abundance versus time for Network A. The abundance of P₁ decreased with end-product inhibition of E_1 activity (Control-ON) versus the no inhibition case (Control-OFF). B: End-product P₂ abundance versus time for Network B. Inhibition of branch point E_6 by end-product P₁ decreased P₂ abundance (Control-ON) versus the no inhibition case (Control-OFF). C: End-product P₁ abundance versus time for Network A. Inhibition of branch point E_6 by end-product P₁ decreased P₁ abundance (Control-ON) versus the no inhibition case (Control-OFF).

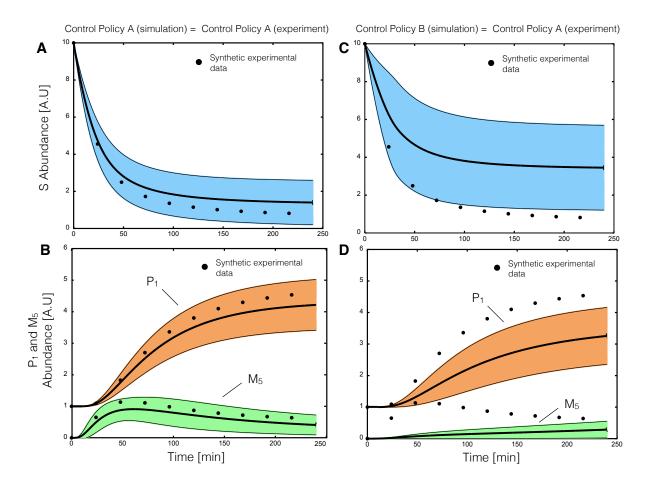

Fig. 5: Parameter estimation from synthetic data for the same and mismatched allosteric control logic using particle swarm optimization (PSO). Synthetic experimental data was generated from a hypothetical parameter set using Network A, where substrate S, end-product P_1 and intermediate M_5 were sampled approximately every 20 minutes. For cases **A,B** 20 particles were initialized with randomized parameters and allowed to search for 300 iterations. **A,B**: PSO estimated an ensemble of parameters sets (N = 20) consistent with the synthetic experimental data assuming the correct enzymatic and control connectivity starting from randomized initial parameters. **C,D**: In the presence of control mismatch (Network B control policy simulated with Network A kinetic parameters) the ensemble of models did not describe the synthetic data.

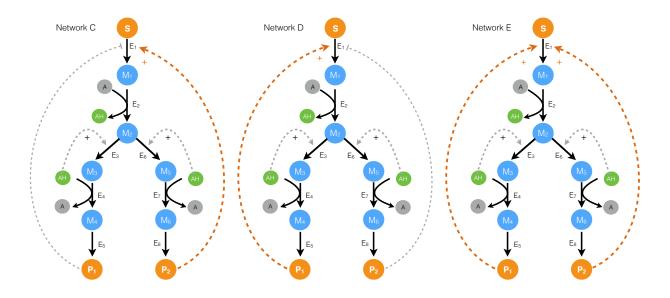

Fig. 6: Schematic of the alternative allosteric control programs used in the structural particle swarm computation. Each network had the same enzymatic connectivity, initial conditions and kinetic parameters, but alternative feedback control structures for the first enzyme in the pathway.

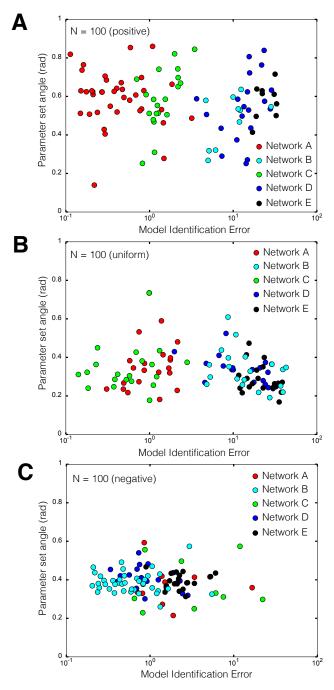

Fig. 7: Combined control and kinetic parameter search using modified particle swarm optimization (PSO). A population of N = 100 particles was initialized with randomized kinetic parameters and one of five possible control configurations (Network A - E). Simulation error was minimized for a synthetic data set (S, end-product P₁ and intermediate M₅ sampled approximately every 20 min) generated using Network A. **A**: Simulation error versus parameter set angle for N = 100 particles biased toward the correct regulatory program (A,B,C,D,E) = (40%, 10%, 20%, 20% and 10%). **B**: Simulation error versus parameter set angle for N = 100 uniformly distributed particles (A,B,C,D,E) = (20%, 20%, 20%, 20% and 20%). **C**: Simulation error versus parameter set angle for N = 100 negatively biased particles (A,B,C,D,E) = (10%, 40%, 10%, 20% and 20%). Network A (the correct structure) was preferentially identified for positively and uniform biased particle distributions, but misidentified in the presence of a large incorrect bias.

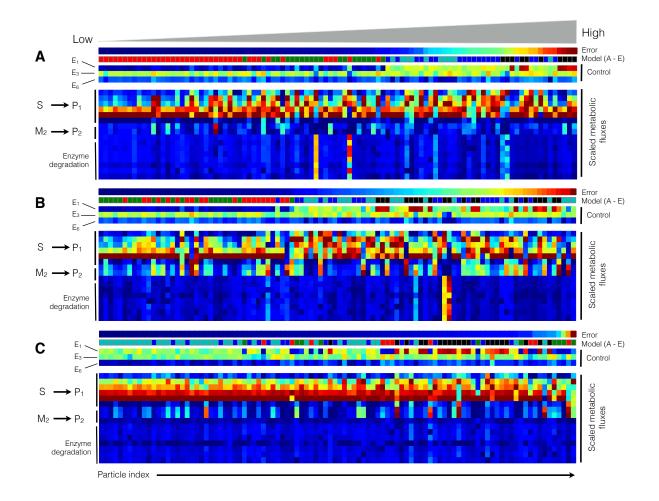

Fig. 8: Metabolic flux and control variables as a function of network type and particle index at t=100 min. The control variables governing E_1, E_3 and E_6 activity and the scaled metabolic flux and were calculated for the positively, uniformly and negatively biased particle swarms (N = 100). The particles from each swarm were sorted based upon simulation error (low to high error). A: Model performance for the positively biased particle swarm as a function of particle index. B: Model performance for the uniformly biased particle swarm as a function of particle index. C: Model performance for the negatively biased particle swarm as a function of particle index. Models with significant control mismatch showed distinct control and flux patterns versus those models with the correct or closely related control policies. In particular, models with the correct control policy showed stronger inhibition of E_1 activity, leading to decreased flux from $S \rightarrow P_1$. Conversely, models with significant mismatch had increased E_1 activity, leading to an altered flux distribution. This is especially apparent in the negatively biased particle swarm.
